Bank specialization and zombie lending

Olivier De Jonghe, Klaas Mulier and Ilia Samarin

Editor

Pierre Wunsch, Governor of the National Bank of Belgium

Statement of purpose:

The purpose of these working papers is to promote the circulation of research results (Research Series) and analytical studies (Documents Series) made within the National Bank of Belgium or presented by external economists in seminars, conferences and conventions organised by the Bank. The aim is therefore to provide a platform for discussion. The opinions expressed are strictly those of the authors and do not necessarily reflect the views of the National Bank of Belgium.

The Working Papers are available on the website of the Bank: http://www.nbb.be

ISSN: 1375-680X (print)
ISSN: 1784-2476 (online)

Abstract

Bank specialization leads to expertise, including knowledge on zombie borrowers and the negative impact they exert on healthy borrowers. This induces specialized banks to reduce zombie lending. The reduction in zombie lending is larger when the scope and opportunity cost of negative spillovers to healthy borrowers is larger; namely, when the fraction of sectoral labor stuck in zombie firms is larger or when the sector is expected to grow faster. Additionally, specialized banks reduce zombie lending less in sectors with higher asset specificity, as zombie firms' default (and potential asset fire sales) could trigger reductions in healthy borrowers' collateral values.

The views expressed in this paper are those of the authors and do not necessarily reflect the views of the National Bank of Belgium or the Eurosystem. All errors are our own.We are highly indebted to Diana Bonfim, Tim Eisert (discussant), Sophie Manigart, Steven Ongena, Farzad Saidi, Enrico Sette (discussant), Joris Tielens, and Tom Vanacker, as well as seminar participants at Ghent University, FINEST 2020, and FIRS 2021 for their valuable remarks and suggestions.

Non-technical summary

Zombie firms recently attracted a lot of attention from researchers and policy-makers. A zombie firm is generally thought of as a poorly performing firm that is unable to service its debt from operating cash flows over a prolonged period but survives thanks to (too) cheap credit from lenders. Recent studies have pointed towards an increasing prevalence of zombie firms as an explanation for Europe's low productivity, low innovation activity, and lack of inflation in the recovery after the financial and sovereign debt crises.

While a lot of this research investigated the impact of zombie lending and zombie firms on the economy, much less research investigated their determinants. Yet, it is this latter insight that is needed to mitigate the zombification of the economy. So far, the literature revealed strong bank capital and on-site inspections of banks as ways to reduce zombie lending. In this paper, we investigate a novel channel that may help to reduce zombie lending, namely bank specialization.

Using granular loan-level data covering over 50 thousand Belgian firms and 54 banks between 2004 and 2018, we convey two interesting and important messages. First, the choice of how zombie firms are identified is important, as it may lead to substantial differences in the estimated zombie population, both in terms of the number of zombie firms and the quality of zombie firms. Compared to a widely-used OECD definition, our cash-flow-based approach signals that there are much fewer zombie firms in the economy than some previously believed (4% of the population instead of 9%). However, those firms that we identify as zombies are of much lower quality and have much poorer prospects than healthy firms.

Second, we provide evidence on how and why bank specialization impacts zombie lending. Banks often specialize in lending to specific sectors and gain sector-specific information through having many interactions with borrowers from the same sector. We argue that such sectoral information advantage also makes banks more aware of zombie firms in the sector as well as more knowledgeable about the negative impact that zombie firms have on healthy borrowers. Our findings show that banks' sector specialization is associated with lower and even reduced credit supply to zombie borrowers. Our analysis shows that this information channel is indeed sector-specific and different from borrower-specific hard (e.g., firm financial statements) or soft (e.g., firm-bank relationships) information.

Moreover, we show that banks' specialization leads to even larger reductions in zombie lending in sectors where healthy borrowers are more likely to forgo growth or suffer from the presence of zombie firms. Namely, in sectors that are expected to grow faster or in sectors where a larger share of employment is stuck in zombie firms. Finally, we find that banks' specialization leads less to reductions in zombie lending in sectors where default of a zombie borrower could trigger a reduction in the asset values of healthy borrowers; namely in sectors with higher asset specificity.

The findings of this study are relevant in the current circumstances of the ongoing COVID-19 crisis when banks' expertise and screening abilities become especially important to identify truly viable firms and negotiate the term of debt restructuring in a way that supports the economic recovery.

TABLE OF CONTENTS

1. Introduction

Recently, zombie firms have attracted the attention of many researchers and policy-makers, especially in Europe. A zombie firm is generally thought of as a poorly performing firm that is unable to service its debt from operating cash flows over a prolonged period of time but survives thanks to (too) cheap credit from lenders. Evidence indicates that the share of such zombie firms increased significantly over the last decades in many European countries (Banerjee and Hofmann, 2020). At the same time, the European economy started resembling the Japanese economy during its "lost decade", for which it has been shown that lending to zombie firms played a contributing role (Caballero et al., 2008). In line with this analogy, recent papers point towards the emergence of zombie firms as an explanation for Europe's low productivity (McGowan et al., 2018; Gouveia and Osterhold, 2018), low innovation and patenting activity (Schmidt et al., 2020), and lack of inflation (Acharya et al., 2020) in the recovery after the financial and sovereign debt crisis.

While a lot of research investigated the impact of zombie lending and zombie firms on the economy[1], much less research investigated their determinants. Yet, it is this latter insight that is needed to mitigate the zombification of the economy. So far, the literature revealed strong bank capital (Giannetti and Simonov, 2013; Acharya et al., 2019, 2020) and on-site inspections of bank regulators (Bonfim et al., 2021) as ways to reduce zombie lending. In this paper, we investigate a novel, bank management-induced channel that may help to reduce zombie lending, namely bank specialization.

Banks often specialize in lending to specific sectors.[2] Such specialization enables them to acquire sector-specific information which improves their ability to assess borrowers' quality and financial prospects beyond what can be derived from borrower-specific hard (e.g., firm financial statements) and soft information (e.g., firm-bank relationships). Banks gain sector-specific information through having many interactions with borrowers from the same sector and, consequently, know those sectors

[1]Most researchers find that zombie firms have a negative impact on healthy firms and the economy. Schivardi et al. (2021), however, find that this is not the case during a crisis period and that in such period it is, in fact, better to keep zombie firms alive to avoid additional reductions in demand (related to employee lay-offs) and disruptions of supply chains (related to the bankruptcy).

[2]See, e.g., Paravisini et al. (2017); De Jonghe et al. (2020); Beck et al. (2021); Blickle et al. (2021) for recent papers on bank sector specialization.

best where they grant most loans.[3]

Previous research has shown that this sectoral information advantage is valuable for banks. Berger et al. (2017) show that it reduces banks' screening and monitoring costs as it reduces their need for audited financial statements. Blickle et al. (2021) and Giometti and Pietrosanti (2019) respectively show that it enables banks to offer loans with more generous terms and less restrictive covenants. De Jonghe et al. (2020) show that banks that faced a funding shock during the global financial crisis relatively shielded borrowers in their specialized sectors.

Besides taking into account hard, soft, and sectoral information to estimate a borrower's repayment probability, banks also take into account spillover effects of lending decisions on incumbent borrowers. Giannetti and Saidi (2019) show that, when a sector is in distress, banks are more likely to provide liquidity if that sector depends largely on that bank. Banks do this because they anticipate the disruptive effects of sectoral distress (e.g., fire sales or asset depletion) and internalize them. As high-market-share banks have a large impact on a sector, granting ample liquidity to firms in a distressed sector prevents the disruptive effects and is therefore optimal (despite each individual firm in a distressed sector perhaps being too risky to lend to).

Given the informational advantage derived from specialization, we assume that banks are more aware of the presence of zombie firms and their impact on healthy borrowers in sectors where they are specialized. Moreover, given that banks also take into account spillover effects on healthy borrowers, we expect banks to provide relatively less credit to zombie firms operating in sectors where they are specialized.

To shed light on this question, we use a unique dataset that combines three data sources of the National Bank of Belgium (Belgium's Central Bank). We first draw firm-bank loan information for the universe of banks and firms in Belgium from the Central Corporate Credit Register. Second, we augment this data with firms' balance sheets and income statements that firms file via the Central Balance Sheet Office. Third, we further augment this data with banks' balance sheets and income statements. The richness of the data enables us to use a comprehensive set of fixed effects. Building

[3]Hence, a bank's sectoral specialization is often proxied by a sector's share in the bank's lending portfolio (De Jonghe et al., 2020; Blickle et al., 2021).

on Khwaja and Mian (2008), we disentangle credit demand from credit supply using firm×year fixed effects. Thus, in all our specifications, we get our identification by comparing how multiple banks with different levels of sectoral specialization adjust their credit supply to the *same* firm/zombie. Our final dataset runs from 2004 to 2018, covers 614,322 firm-bank-year observations from 54 banks and more than 50 thousand firms.

Our results at the extensive margin show that, holding credit demand constant, zombie firms are less likely to see an increase in their outstanding credit amount (and thus receive a new loan) from a bank that is specialized in lending to the zombie's sector. Results at the intensive margin confirm this. For a given level of credit demand, a zombie firm's credit growth is lower from a bank that is specialized in lending to the zombie's sector than from a bank that is not specialized. Our specifications also include bank×year fixed effects to absorb bank-time specific shocks as well as time-invariant bank characteristics. Our results can thus also be interpreted as follows: banks reduce their credit supply to zombie firms more if that zombie operates in a sector where the bank is more specialized. Both interpretations, however, are in line with the idea that banks are more aware of and concerned about the impact of zombie lending in sectors where they are specialized.

Next, we shed light on the characteristics of this specialization-induced information advantage. First, to confirm that the effect of sectoral specialization is about a sectoral information advantage and spillover concerns, and not about borrower-specific (hard or soft) information, we augment our baseline credit model with specialization×firm financial characteristics, firm-bank relationship characteristics, and zombie×firm-bank relationship characteristics. These adjustments have little to no impact on the baseline results.

Second, we show that bank specialization leads particularly to less credit supply to zombie firms when i) the risk of negative spillovers of zombie firms is high in the sector and ii) the cost of negative spillovers of zombie firms is high in the sector. Healthy borrowers compete with zombie firms for resources and market share. This competition is distorted if zombie firms make up a significant fraction of the sector, and not distorted if they make up a negligible fraction. Our results show that banks reduce zombie lending significantly more in specialized sectors when the share of labor that is stuck in zombie firms in the sector is higher. Furthermore, the opportunity cost of such distortion is likely to be higher for borrowers in fast-growing sectors. Our results show that banks

reduce zombie lending significantly more in specialized sectors when the sector exhibits higher sales growth.

Third, we show that the informational advantage and spillover concerns do not always imply reduced credit supply for zombie firms (or are not always sufficiently strong to imply this). For instance, we find that the effect of bank specialization on credit to zombie firms is less pronounced in sectors with higher asset specificity. Such assets have a lower redeployability outside of the sector and therefore have a lower liquidation and collateral value. Specialized banks reduce zombie lending less in such sectors due to the contagion risk that zombie default poses on the collateral value of healthy borrowers' assets (Giannetti and Saidi, 2019; Almeida et al., 2011; Acharya et al., 2007). Furthermore, the relative size of the zombie borrower in the bank's portfolio also seems to matter. Zombie firms that are large from the bank's perspective, enjoy a significantly higher credit supply that is not fully offset by the effect of sector specialization; even though we find that the effect of specialization is stronger for zombie firms that are large in the bank's portfolio.

In addition to shedding light on the role of bank specialization for credit supply to zombie firms, our paper proposes some important modifications to the widely-used OECD definition to identify zombie firms using firms' financial statements. The OECD measure (McGowan et al., 2018) defines a zombie as a mature firm whose EBIT-to-interest expense ratio is below one for three consecutive years. Our first modification is to start from a firm's recurring cash flows rather than from a firm's EBIT. Most importantly, this implies abstracting from depreciation and amortization as well as including recurring financial revenues (from liquid assets or intercompany loans, for instance). Starting from EBITDA and including recurring financial revenues, therefore, avoids wrongly classifying healthy firms as zombies: firms with recent large investments (high EBITDA, low EBIT firms (Rodano and Sette, 2019)), firms with high cash levels (typically small firms), and firms that grant intercompany loans (typically large firms).

Our second modification intends to bring more persistence to identified zombies and to avoid wrongly classifying zombie firms as healthy. We identify firms as zombies if the three-year cumulative operating and financial cash flows are insufficient to cover the three-year cumulative interest expenses. We thus depart from the OECD definition, who use an EBIT-to-interest expense rule for three consecutive years. Compared to the OECD definition, our definition estimates a much more

moderate and less cyclical share of zombie borrowers in the economy (4% instead of 9%). There is thus a large set of reasonable quality borrowers that our measure identifies as healthy firms but that the OECD definition picks up as zombie firms.

The average zombie identified according to our definition is significantly more risky and less viable than the average zombie identified according to the OECD definition, and hence might induce larger negative spillover effects. Specifically, the differences in quality pertain to firm profitability, leverage, having negative equity, past firm growth, future sales growth, investments in tangible assets, etc. Our modifications not only show a more credible picture of zombie firms in an economy, but this also matters for identifying the role that bank specialization plays for zombie lending.

We contribute to the academic literature in at least three ways. First of all, we contribute to the literature on zombie firms, and in specific the literature that analyzes the determinants of zombie lending. Most studies focus on the role of bank capital (Caballero et al., 2008; Giannetti and Simonov, 2013; Acharya et al., 2019, 2020) or overall bank health (e.g., Andrews and Petroulakis, 2017; Storz et al., 2017). Recently, Bonfim et al. (2021) show that on-site regulatory inspections also significantly determine banks' incentives to renew loans to zombie firms. We show a novel determinant that alleviates zombie lending, namely bank specialization.

Secondly, we contribute to the literature on bank specialization (versus bank diversification). One view in this literature is that banks should diversify their lending portfolio as much as possible (e.g., Diamond, 1984). However, recent theoretical arguments and empirical evidence claim substantial benefits of specialization. A bank that is lending more to a given sector, learns proprietary sector-specific information which gives the bank an information advantage. As a result, sectoral lending specialization alleviates information asymmetry (Berger et al., 2017) and enables banks to better monitor and screen their borrowers (e.g., Sharpe, 1990). Banks have incentives to protect borrowers in specialized sectors to maintain their information advantage (Müller, 2020), and indeed, did so during the interbank freeze after the Lehman Brothers collapse (De Jonghe et al., 2020). Bank specialization has also been shown to correlate with lower credit risk (Jahn et al., 2016), higher performance (Acharya et al., 2006), higher distance-to-default (Beck et al., 2021) and higher financial stability (Acharya et al., 2006; Beck et al., 2021). Our results are in line with this recent evidence and show that bank specialization leads to lower lending to zombie firms to reduce the

risk of negative spillovers on healthy borrowers. As a result, banks improve their lending portfolio.

Finally, we add to the debate of how zombie firms should be measured. Researchers have identified zombie firms in many different ways (Caballero et al., 2008; McGowan et al., 2018; Acharya et al., 2019; Schivardi et al., 2020; Bonfim et al., 2021). While we do not impose a solvency criterion in our zombie definition, we are picking up firms with higher leverage (Acharya et al., 2020), that are more likely to have negative equity (Bonfim et al., 2021), and have lower growth potential (Banerjee and Hofmann, 2020), due to lower investment in physical and human capital and lower future sales growth. Also importantly, we end up with a more moderate size of the zombie population. This is in line with the latest discussion papers that show that the zombie population in certain countries is not as dramatically high as it had been shown before.[4]

2. Data

We draw data from three unique data sources available at the National Bank of Belgium. The first source is the Corporate Credit Register. It records, at a monthly frequency, all loans granted by Belgian financial institutions to firms operating in Belgium. This database allows us (i) to compute credit growth at the intensive and extensive margin, (ii) to isolate credit supply from credit demand by (mainly) focusing on multiple-bank borrowers, and (iii) to compute banks' sector specialization in the corporate credit market. We aggregate the credit exposures at the firm-bank-year level before matching them with the second data source.

The second data source is the Central Balance Sheet Office. It collects balance sheets and income statements of *the universe* of Belgian enterprises. Firms have to file financial statements on an annual basis. This dataset also contains a firm's date of incorporation, legal form, and the main economic sector a firm operates in. The richness and completeness of this database allow us to construct our new zombie definition. Finally, we obtain balance sheets and income statements of financial institutions. Banks report these data following the so-called Scheme A, and we use the latest financial statement reported in a given year.

We apply the following filters. Since we analyze bank lending to the real economy, we exclude

[4]See, e.g., Rodano and Sette (2019) for evidence on Italy or Favara et al. (2021) for the U.S.

firms from the financial and insurance sector, public administration and education sectors, activities of extraterritorial entities, and activities of households as employers (NACE sectors K, O, P, T, U). Additionally, we exclude micro-firms from the analysis due to different reporting requirements. Micro firms are defined as firms who have, on average over the sample period, less than 10 FTEs and less than 350,000 euro in total assets. We also exclude rare and highly specific legal forms.[5] Finally, to be consistent throughout all sampled years (2004-2018), we exclude credit exposures below *25,000* Euros.[6], but these exposures below 25,000 Euros account for just over 1% of total corporate credit.

Merging these three sources and applying the aforementioned filters results in a dataset containing *54* banks lending to more than *50* thousand multiple-bank firms over the sample period 2004 to 2018. All tables and figures in this paper are based on this sample of multiple-bank borrowers unless explicitly stated otherwise. Table A.1 in Appendix provides information on the definition and construction of variables used throughout the paper, whereas Table B.1 contains summary statistics of these variables.

3. Who Are the Zombie Firms?

A zombie firm is a mature, consistently underperforming, and unproductive firm that is not able to repay its debt. These firms have a marginal return on capital that is below the risk-adjusted market cost of capital (Schivardi et al., 2021), and would -barring external support- exit the market in a frictionless economy. Due to market failures, zombie firms can stay alive and banks are often blamed for helping them. While there is more or less agreement on the definition of zombie firms, there is an abundance of empirical proxies.

Caballero et al. (2008) identify zombie firms as those who received subsidized credit, which implies a lower interest rate than the interest rate paid by the highest quality borrowers in the

[5]Specifically, we keep the following legal forms in the sample in the descending order based on the frequency in the sample (in Dutch): Besloten Vennootschap met Beperkte Aansprakelijkheid, Naamloze Vennootschap, Besloten Vennootschap, Coöperatieve Vennootschap, Commanditaire Vennootschap op Aandelen, Coöperatieve Vennootschap, Gewone Commanditaire Vennootschap, Coöperatieve Vennootschap met Onbeperkte Aansprakelijkheid, Vennootschap onder Firma, Coöperatieve Vennootschap met Beperkte Aansprakelijkheid, bij wijze van Deelneming, Besloten Vennootschap van publiek recht. These legal forms account for 99% of the total population of enterprises.

[6]Before April 2012, there was a reporting threshold of *25,000* Euro, above which exposures have to be reported

market. Andrews and Petroulakis (2017) and McGowan et al. (2018) define zombies as firms that are at least 10 years old and have had the interest coverage ratio, measured as the ratio of earnings before interests and taxes (EBIT) to financial expenses, below one for at least three consecutive years. We refer to this as the OECD definition. Other researchers have identified zombie firms using (a combination of) firm performance measures, such as: (i) firm profitability (e.g., Schivardi et al., 2021), (ii) negative equity (Bonfim et al., 2021), (iii) low interest coverage ratio (e.g., Andrews and Petroulakis, 2017), or (iv) leverage (Acharya et al., 2020).

3.1. New approach to classify zombie firms

We suggest a new approach to identify zombie firms. Our approach is based on *recurring cash flows* and *longer term, structural underperformance*, and builds on the OECD definition. A firm is classified as a zombie if three conditions are met: (i) the firm's 3-year accumulated cash flows fall below its 3-year accumulated interest expenses, (ii) yearly cash flows are below interest expenses in at least 2 of these 3 years, and (iii) the firm is at least 10 years old.

We focus on *recurring cash flows*, which implies two departures from the OECD definition. The first difference is the use of EBITDA rather than EBIT to measure recurring operational income. As interest expenses are a cash outflow, operational earnings (EBIT) is not a good indicator of a firm's ability to service its debt due to its inclusion of components that do not generate cash-flows, in particular depreciation and amortization. Furthermore, deprecation and amortization practices are highly sector-specific (see Figure C.1 in Appendix where we plot the sector-average share of depreciation and amortization in EBITDA). This distorts comparisons across sectors and countries (to the extent that they differ in their industrial composition). Finally, firms with high depreciation in the current period (and thus low EBIT relative to EBITDA) tend to have invested heavily in the previous years, which is counter-intuitive as zombie firms are expected not to be able to invest (Storz et al., 2017).

The second difference is that we add recurring financial income to operating income to measure a firm's recurring cash flows. Recurring financial income (of which dividends and income earned on current assets are the most important sources) can also be used to service interest expenses. In addition, recurrent financial revenues are more prevalent in large firms, and excluding these

revenues might induce biases as well as inflate the share of capital and labor stuck in zombies. Finally, recurrent financial revenues are sector-specific and should thus be properly accounted for (Figure C.1 in Appendix plots the sector-average share of recurring financial revenues in EBITDA.).

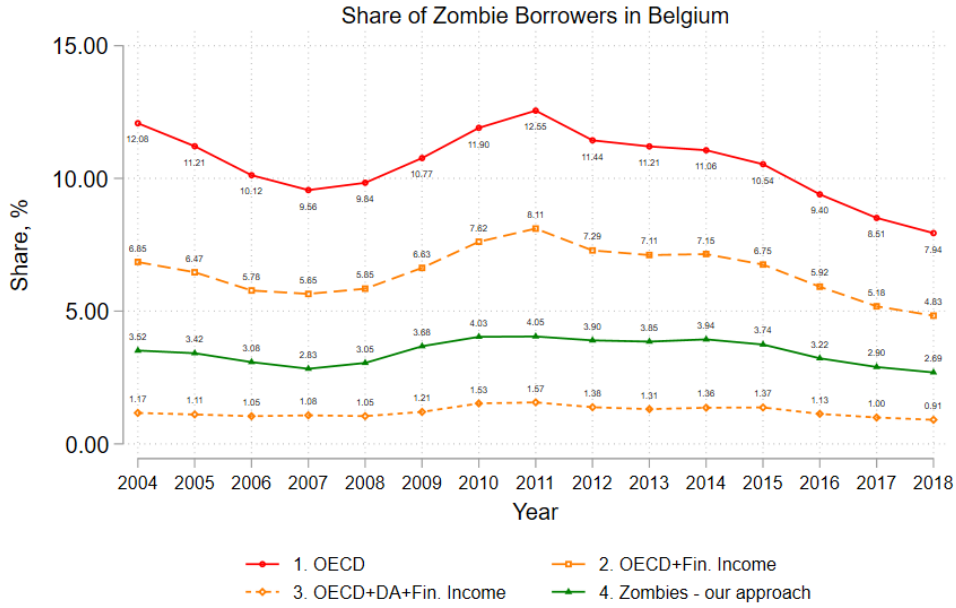
Further, our identification requires that recurring cash flows are *structurally* insufficient to meet interest expenses. Rather than assessing the condition year-by-year over a 3-year horizon (as in the OECD concept), we assess whether 3-year cumulative cash flows are insufficient to cover 3-year cumulative interest expenses. Doing so, we avoid incorrectly classifying firms as healthy, if they (possibly by luck) have a one-off improvement in cash flows or one-off reduction in interest expenses[7]. Using cumulative cash flows and interest expenses over a period of three years is akin to Schivardi et al. (2021), who suggest using a moving-average-based approach for the numerator and denominator of the interest coverage ratio. To avoid, on the other hand, incorrectly classifying firms as zombies due to one exceptionally bad year, we additionally impose that operating and financial cash flows should be less than interest expenses in at least 2 of the previous 3 years.

Each adjustment may have important consequences for classifying a firm as a zombie or not. To shed light on the impact of these adjustments, we plot in Figure 1, the impact of each of these adjustments on the share of zombies borrowers. Starting from the OECD definition (red line on top), we see that adding financial revenues (orange, long-dash) already has a sizeable impact on the number of firms identified as zombies. Further, using cash flows (EBITDA) rather than EBIT substantially reduces the number and importance of zombies (see also Rodano and Sette (2019) for a similar impact when applied to Italian firms). Finally, assessing cash flow deficiencies over a three-year horizon, rather than on a year-by-year basis, leads to a substantial increase in the number of zombie firms (but still substantially less than using the OECD definition). It is important to mention that these adjustments mainly lead to a level shift in the number of zombies, while the time series evolution of our measure (green line) and the OECD measure (red line) is very similar. Prior to the global financial crisis, the share of zombie borrowers was decreasing, followed by a run-up leading to a peak in 2011 and a gradual decrease afterward. The amplitude of the cycle is, however, smaller when using our definition.

[7] An example of the latter are debt moratoria installed by countries during the COVID-19 pandemic, which led financial institutions to allow for temporary debt renegotiation and reducing financial expenses

Figure 1: Fraction of zombie borrowers: step-by-step definition adjustments

This figure depicts the impact of every adjustment made to the original OECD definition on the fraction of zombie borrowers. The red solid line shows the fraction of zombie borrowers identified by the OECD definition. The long-dashed orange line shows the impact of accounting for recurrent financial income. The short-dashed line shows the impact of accounting for recurrent financial income and adding back depreciation and amortization. The solid green line shows the fraction of zombie borrowers identified after introducing all adjustments. The sample includes yearly data of firms borrowing from more than one bank between 2004 and 2018.



3.2. Zombie firms versus low quality firms

In the previous subsection, we introduced our zombie definition and showed what the adjustments implied for the number of firms identified as zombies (vis-à-vis the OECD definition). In this subsection, we document what these adjustments imply for the type of firms identified as zombies. Comparing zombies according to our definition (Z) with the OECD definition (Z^{OECD}) partitions the sample into four groups: (i) firms identified as zombies under both definitions, (ii) firms identified as zombies according to our definition but as healthy according to the OECD definition, (iii) firms identified as zombies using the OECD definition, but as healthy according to our definition, (iv) healthy firms under both approaches. The number of firms in each group is respectively, 2.4%, 1.0%, 8.0%, and 88.6% of the sample (275,122 firm-year observations).

Using regression analysis, we are comparing whether and how firms in each of these four groups

differ in terms of solvency and risk, profitability, growth of tangible assets and employment, and current and future sales growth. The regression analysis includes Sector×Year and Location×Year fixed effects to net out sectoral or regional differences in firm characteristics and performance. The results are reported in Table 1 and the reported coefficients should be interpreted as deviations from the baseline group, i.e., firms identified as zombies under both definitions (Z=1 and Z^{OECD}=1).

Table 1: Firm characteristics and firm growth: differences across zombie types

This table shows the results of regression analysis comparing four groups of zombie and healthy firms across several dimensions. The dependent variables are equity to total assets ratio (Column 1), a dummy equal to 1 if firm's equity is negative and 0 otherwise (Column 2), EBITDA to total assets ratio (Column 3), Altman Z score (Column 4), growth of tangible assets (Column 5), growth of employment (Column 6), contemporaneous sales growth (Column 7), and the one-year ahead growth of sales (column 8). The independent variables are dummies that identify one of the four groups of firms. Z=1 & Z^{OECD}=0 equals 1 if a firm is identified as a zombie according to our definition but not according to the OECD definition, and 0 otherwise. Z=0 & Z^{OECD}=1 equals 1 if a firm is identified as a zombie according to the OECD definition but not according to our definition, and 0 otherwise. Z=0 & Z^{OECD}=0 equals 1 if a firm is not identified as a zombie according to either definition, and 0 otherwise. The omitted reference category includes firms that are identified as zombies according to both definitions. The sample includes yearly data of firms borrowing from more than one bank between 2004 and 2018. Sector-year and location-year fixed effects absorb time-varying sector- or location-specific differences in the dependent variables. Sectors are defined at the two-digit NACE level. Location is defined at the two-digit postcode level. Standard errors are clustered at the sector-year level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

Sector×Year FE	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Location×Year FE	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

First of all, our approach picks up a set of firms (Z=1 & Z^{OECD}=0), representing 1% of the sampled firms, which are very similar (both economically and statistically) to the baseline group, i.e., zombies under both definitions. However, under the OECD definition, these firms would be pooled together with the set of healthy firms (last row), from which they differ substantially and significantly.

Secondly, and importantly, a sizeable number of firms (8.0% of the sample) are classified as

zombies according to the OECD definition, but not according to ours (Z=0 & Z^{OECD}=1). We find that these firms substantially outperform the benchmark group in terms of solvency, profitability, investment, and employment growth as well as current and future sales growth. In fact, their characteristics are much closer to those of healthy firms than those of zombie firms. They could thus be considered as lower-quality healthy firms, much rather than zombie firms.

Thirdly, compared to the baseline group, firms that are classified as healthy under both definitions (i.e., Z=0 & Z^{OECD}=0) are substantially better capitalized, have a much lower incidence of firms with negative equity and are substantially more profitable; resulting in much higher Altman Z scores. These healthy firms also invest more in physical and human capital and exhibit better future performance (as measured by sales growth).

The results in Table 1 also allow us to make some qualitative comparisons with studies using alternative concepts to identify zombies. First, we show that that the zombie definition used by the OECD mixes zombies with low-quality, but non-zombie firms and find that the ratio of zombies (Z=1) to zombies and low-quality firms (i.e., Z=1 + Z^{OECD}=1) is only 30%. Using a different measurement approach, Acharya et al. (2020) obtain a similar conclusion using a European sample of firms. Second, without imposing a solvency criterion in our zombie definition, we are picking up firms with higher leverage (Acharya et al., 2020), that are more likely to have negative equity (Bonfim et al., 2021), and have lower growth potential (Banerjee and Hofmann, 2020), due to lower investment in physical and human capital and lower future sales growth.

3.3. Resources sunk in zombies and impact on healthy firms

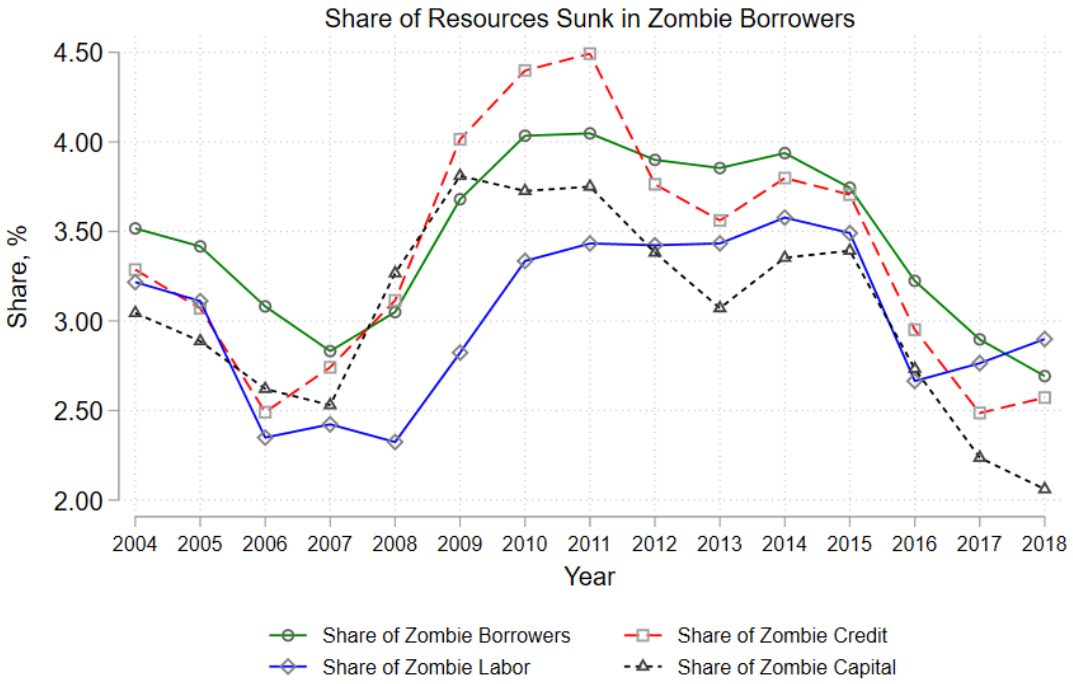
Figure 1 already showed the dynamics of the fraction of zombie borrowers in Belgium between 2004 and 2018. In Figure 2, we plot the evolution of resources allocated to (or 'sunk' in) zombies and depict three lines (in addition to the fraction of zombie borrowers): the share of capital (fixed tangible assets), labor force (FTEs), and bank credit sunk in zombie borrowers.[8]

We can see an increase in the zombie population during and after the financial crisis in the years 2008-2011. After that, the zombie population started to decline slowly. The rise of zombies during

[8]To mitigate the effect of a few extremely large borrowers, we drop values of capital, labor, and credit exceeding the value of the 99th percentile in a given year.

Figure 2: Share of zombie firms in Belgium

This figure plots the evolution of the fraction of (i) zombie borrowers (solid green line); (ii) capital sunk in zombie borrowers (dashed red line); (iii) labor force sunk in zombie borrowers (solid blue line); (iv) bank credit granted to zombie borrowers (dashed black line). Capital is proxied by fixed tangible assets. Labor is proxied by FTEs. The sample includes yearly data of firms borrowing from more than one bank between 2004 and 2018.



the crisis has also been found in other European countries (McGowan et al., 2018). The share of credit sunk in zombies exhibit similar dynamics as the share of zombie borrowers but with a larger amplitude. In most years, the share of capital and labor sunk in zombies is less than the share of credit allocated to zombies. On the one hand, it is reassuring that less real resources than financial resources are sunk in zombies. On the other hand, the credit sunk in zombies (although less used for investments in physical and human capital) may negatively affect the performance of healthy firms competing with these zombies (for credit and market share); a phenomenon called *zombie congestion*. Zombie congestion may happen through at least two channels. Firstly, a larger amount of credit granted to zombie borrowers limits the amount of credit available to healthy firms that are willing to take a bank loan. Secondly, as bank credit helps zombie firms to stay alive and take up the market share, it slows down business dynamism and negatively affects competition (e.g.,

McGowan et al., 2018) and product pricing (Acharya et al., 2020).

Prior research shows a robust, negative relationship between the growth of healthy firms and the share of zombie firms in their sector (see, e.g., Caballero et al. (2008) who show this for Japan and McGowan et al. (2018) who document it for EU firms). In Table E.1 of Appendix, we document that such relationships are present in the Belgian data as well. Healthy borrowers exhibit higher growth in tangible assets, in employment, in current and future sales. However, the growth of healthy borrowers will be smaller if they operate in sectors where a larger fraction of credit is granted to zombie firms. Note that Schivardi et al. (2020) document a serious, and difficult to solve, identification problem in such regressions. They even conclude that the correlation between healthy firms' performance and zombie presence might be mechanical and biased. Solving this identification problem is not the purpose of the paper and therefore, the results in Table E.1 are indicative and only present correlations and not causal evidence. Moreover, as the direction and magnitude of the bias are unclear and context-specific (Schivardi et al., 2020), assessing the economic magnitude of the coefficients is meaningless.

4. Bank specialization and credit supply to zombies

4.1. Empirical specification

Our goal is to analyze the role of bank specialization in zombie lending. To be more specific, we are investigating whether the effect of bank specialization on credit supply is different for zombie firms than for healthy firms. Econometrically, we estimate the following baseline equation:

$$y_{ibt} = \beta_1 \ Specialization_{bjt-1} + \beta_2 \ Z_{it} \times Specialization_{bjt-1} + \nu_{it} + \upsilon_{bt} + \epsilon_{ibt} \quad (1)$$

The dependent variable y_{ibt} is one of three measures of credit growth. First, *New Loan* is a dummy variable that equals one if credit growth for a firm i with bank b in year t is positive, and zero otherwise. It measures, for existing borrowers, whether a new loan has been added or an existing limit has been increased. Next, we measure intensive margin credit growth in two alternative ways. $\Delta Ln(Credit)$ is the annual credit growth, defined as the logarithmic difference between the

outstanding credit amount, at the firm-bank level, in year t and year *t-1*. $\Delta Credit/Assets$ is the absolute change in the outstanding credit amount, at the firm-bank level, from year *t-1* to year t scaled by the borrower's total assets in *t-1*. With these measures, we only focus on the *intensive* margin of lending, i.e., changes in the volume of lending to existing borrowers, as the concern is that banks keep zombie firms alive (rather than starting new relationships with zombie firms).

Z_{it} is a zombie identifier, which equals one if a firm i is identified as a zombie according to our metric in year t. Bank specialization, $Specialization_{bjt-1}$, or sectoral lending concentration, is the fraction of a bank's b credit granted to a sector j in the bank's total corporate lending portfolio, measured in year $t-1$. A sector j is measured at the two-digit level of the NACE classification. We interact the zombie identifier with bank specialization to grasp whether the effect of specialization on credit supply differs for zombie firms. Table B.1 and Figure F.1 in Appendix show that there is sizeable variation in sector specialization across the sample, but also between banks within a sector-year. Given the inclusion of a large set of fixed effects, see infra, it is the latter source of variation that is relevant for estimating and identifying the effect of specialization on credit supply to zombie firms.

The baseline specification in Equation 1 includes an extensive set of fixed effects. We resort to the most stringent specification using the methodology of Khwaja and Mian (2008). Firm-time fixed effects (ν_{it}) capture any observed and unobserved firm-specific credit demand effects. Doing so, we only include firms that simultaneously borrow from two or more banks. This is stringent in the setting of Belgium, as many firms in Belgium borrow from only one bank. However, as credit demand might differ substantially between zombie firms and healthy firms, it is crucial to isolate demand from supply and therefore resort to the approach of Khwaja and Mian (2008). Note that this firm-time fixed effect also absorbs the direct effect of Z_{it} on y_{ibt} and is therefore not separately included in Equation (1). Additionally, we include bank-time fixed effects (υ_{bt}) to capture all observed and unobserved bank-specific determinants of lending.

The coefficients of interest are β_1 and β_2. β_1 is expected to be positive. Banks tend to provide more credit to firms operating in sectors in which the bank is specialized (De Jonghe et al., 2020). The coefficient β_2 of the interaction between specialization and the zombie identifier is expected to be negative. A negative sign indicates that zombie firms benefit less (or are penalized) in terms of

credit supply due to bank specialization. Alternatively, a zombie firm borrowing from two banks will experience a lower credit supply from its specialized lender vis-à-vis its uninformed lender.

4.2. Main results

Table 2 presents the results of estimating Equation 1 on the sample of multiple-bank borrowers over the period 2004-2018. The sample includes *614,332* bank-firm-year observations. Bank specialization has been standardized to facilitate the interpretation and economic impact assessment. We find, first of all, a positive and statistically significant coefficient of sector specialization. This is in line with existing evidence and suggests that banks are on average more likely to increase lending to firms in sectors they specialize in. Secondly, and of crucial interest for our analysis is the negative coefficient on the interaction term between sector specialization and the zombie indicator, in each of the three columns.

Table 2: Average effect of bank specialization on zombie lending

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization and the interaction between bank specialization and a dummy indicator for zombie firms. The sample includes yearly bank-firm level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Bank specialization has been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

	(1) New Loan	(2) ΔLn(Credit)	(3) $\frac{\Delta\text{Credit}}{\text{Assets}}$

N. of clusters	1774	1774	1774
Firm×Year FE	Yes	Yes	Yes
Bank×Year FE	Yes	Yes	Yes

In the first column, the coefficient on the interaction term is smaller (in absolute value) than the main effect of specialization, indicating that the beneficial effect of specialization on credit

supply is much less pronounced for zombie borrowers. Zombie borrowers are less likely to receive a new loan from their specialized lender compared to their less specialized lender. The effects of specialization are also economically significant. A one standard deviation increase in specialization leads, for a healthy firm, to a 2.01 percentage point higher probability of obtaining a new loan (from its current lenders). This is sizeable, given that the average probability of receiving a new loan in the sample is 25.61% (see the summary statistics in Table B.1). However, the results in Column 1 of Table 2 also suggest that the probability of receiving a new loan still increases but is on average 76% ($= 1-(2.01-1.53)/2.01$) lower for a zombie borrower relative to a healthy borrower operating in the same sector given the same increase in bank specialization.

In the second and third columns, the coefficients on the interaction term are larger (in absolute value) than the coefficients on specialization. This implies that an increase in sectoral specialization even *reduces* credit for zombie borrowers. In the case of the credit growth relative to firm size (Column 3), while a one standard deviation increase in bank specialization leads to an average increase in relative credit amount of almost 0.11 percentage points (which is well above the sample mean of credit growth), a zombie borrower from the same sector faces a credit reduction, which is *twice* larger in magnitude (−0.23=0.11-0.34).

Overall, our findings reveal an important role of bank sector specialization in zombie lending. On the one hand, more credit is granted to borrowers operating in sectors, in which banks are more specialized. This finding is in line with the existing literature (e.g., Paravisini et al., 2017; De Jonghe et al., 2020), which shows that banks expand lending to sectors where they are more specialized. On the other hand, we shed light on a novel aspect of bank sector specialization that has not been discussed before. We find that bank specialization is associated with lower zombie lending. Using our sample of firms borrowing from multiple banks, we show that a zombie firm faces a lower credit supply at the bank that is more specialized in the borrower's sector.

These main results are in line with the interpretation that banks gain an informational advantage from specialization. By concentrating lending in a certain sector, banks obtain more proprietary sector-specific information (Berger et al., 2017), which leads to a reduction in the cost of monitoring (Diamond, 1984) and better screening abilities (Dell'Ariccia et al., 1999). As a result, banks specialized in a certain sector are (i) better able to identify zombie borrowers and distinguish them

from healthy firms and firms who temporarily perform poorly, (ii) better able to assess the long-term financial prospects of their borrowers, and (iii) understand better the impact that zombie firms have on the long-term financial prospects of their healthy borrowers.

In section 6, we document in detail that this baseline specification is **robust** to (i) firm-bank matching and credit demand, (ii) aggregate analysis, (iii) alternative measures of specialization, and (iv) confounding factors related to bank health and financial crises.

4.3. Zombies versus low-quality firms

Acharya et al. (2020) document that zombie firms constitute less than 25% of all low-quality firms. Likewise, we find that only 30% of the firms identified as zombies according to the commonly used OECD definition are still labeled zombies after our adjustments. Moreover, comparing these along many relevant dimensions (see Table 1) indicates that low-quality, non-zombie firms (Z^{OECD}=1 & Z=0) are more akin to healthy firms than to zombie firms. Hence, we would expect that the impact of information acquisition (through specialization) on credit supply to low-quality firms is more similar to the baseline effect (i.e., for healthy firms) than the effect for zombie borrowers.

In Table 3, we show results of augmenting the baseline specification with an interaction term of bank specialization and a dummy that is one for low-quality, non-zombie firms, and zero otherwise (i.e., a dummy capturing the firms for which Z^{OECD}=1 & Z=0). We find that the coefficient in the second line has the expected negative sign, but is only significant in the first column. Moreover, even in the first column, the moderating effect is substantially weaker for the lower quality firms (-0.53) than for the zombie firms (-1.58).

An important insight from this additional analysis is that using measures that pool low-quality firms with zombie firms might lead to biased results and incorrect conclusions on how banks use their information advantage to reallocate credit from zombies towards healthier firms in sectors in which they are specialized.

Table 3: Average effect of bank specialization on zombie lending: zombies vs. low-quality firms

This table shows the effect of bank specialization on the credit growth of healthy firms, low-quality firms, and zombies. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization and the interactions between bank specialization and two dummy indicators. First, an indicator for low-quality firms, which equals 1 if a firm is identified as a zombie according to the OECD definition but not according to ours and 0 otherwise. Second, an indicator for zombie firms, which equals 1 if a firm is identified as a zombie according to our definition and 0 otherwise. The sample includes yearly bank-firm level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Bank specialization has been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

5. Characteristics of the Specialization Channel

In this section, we explore various characteristics that help to understand how the bank specialization channel works in reducing zombie lending.

5.1. Specialization and sectoral information advantage

We argue that specialization-induced information advantages allow banks to better screen and monitor their borrowers and understand sectoral dynamics. Not only are specialized banks thus better able to identify zombie borrowers, but they may also better understand zombies' impact on healthy borrowers. However, sector specialization need not be the only source of superior information. Soft information acquired by banks throughout the relationship with borrowers (Petersen and Rajan, 1994) is also an important determinant of firms' access to credit (Bolton et al., 2016; Petersen

and Rajan, 1995). If banks lack expertise in a sector and are therefore deprived of sector-specific information, they may invest more in firm-specific information. The two sources of information may thus act as substitutes and not adequately controlling for firm-specific soft information might bias our main finding.

Our strategy for testing whether the sector-specific soft information obtained through specialization drives the effect of specialization on zombie lending is to horse-race our baseline model in Equation 1 against specifications enriched with alternative sources of information that may affect the bank's decision to roll over zombie loans. If the impact of additional variables on the interaction term between the zombie identifier and specialization is limited, it would serve as evidence that the relationship between sector specialization and zombie lending is indeed driven by the sector-specific information that banks learn about the borrowers in specialized sectors.

First, we augment the baseline model with firm-bank-specific soft information that banks learn over the course of the relationships with their borrowers. On the one hand, by having closer and stronger relationships with their borrowers, banks are better able to screen the quality of the borrowers (e.g., Bolton et al., 2016). On the other hand, by having a long relationship with their borrowers, banks may even continue to lend to poorly performing firms such that they can extract more profits from them later on (Sharpe, 1990; Schäfer, 2019). Hence, we introduce to the specification a variable *Ln(Relationship)* measuring the relationship length since the first time a bank lent to a given borrower. Additionally, we control for private information that can be learned by the primary lender (e.g., Ioannidou and Ongena, 2010) by adding a variable *Bank Share* that measures the share of credit given by the bank in the borrower's total outstanding credit. Finally, we also control for a bank's market share in a given sector (*Presence*) to account for a bank's pricing power as well as for a bank's willingness to internalize losses in markets where the bank is more present (Giannetti and Saidi, 2019). To rule out that banks reduce credit supply to zombie firms in specialized sectors because they have more firm-specific soft information about their borrowers in specialized sectors or because they have more market power over their borrowers in specialized sectors[9], we also interact our zombie indicator with the above-defined variables.

[9]The correlation between sectoral market share and sectoral specialization is rather modest ($corr = -0.06$). While the former measures how important a bank is for a sector, the latter measures how important a sector is for a bank.

Second, besides controlling for soft information, we introduce interaction terms between bank specialization and hard information on risk (at the firm-year level). What is important to note here is that these interaction terms are not to be interpreted whether banks adjust credit supply differently to firms according to these firm characteristics (because we already include firm×year fixed effects which absorb this). It should, however, enable us to assess whether banks' sector specialization incentivizes banks to reduce credit to zombie borrowers because banks learn more about them and their impact on healthy borrowers, or whether specialization simply enables banks to better understand firm-specific risk. If the latter is true, then the interaction between sector specialization and our zombie indicator in the baseline regression was spurious due to the zombie indicator being related to hard firm characteristics that reveal high risk. If the former is true, then adding the interactions between specialization and the hard firm characteristics should not affect the interaction between zombie and specialization. The hard-information variables include the firm's lagged total assets, leverage, return on assets, current ratio, and age.

The results of this exercise are presented in Table 4. In columns 1 to 3, we include only the soft information controls; in columns 4 to 6, we include only the hard information controls; in columns 7 to 9, we include both soft and hard information controls. The results of this test show that bank specialization remains an important and significant determinant of zombie lending, even when we explicitly account for other common sources of soft and hard information. The results of this exercise support the conclusion that higher sector specialization provides the bank with a separate source of proprietary information, which is bank-sector specific and soft in nature.

5.2. Fear of missing out: zombie spillover risk

The existing literature provides ample evidence of negative zombie spillover effects. Zombie firms hamper growth (Caballero et al., 2008), business dynamism (Andrews and Petroulakis, 2017) and innovation (Schmidt et al., 2020) of healthy firms operating in congested sectors. If bank specialization provides banks with superior information about the sector, they should have more incentives to limit zombie lending when the scope *and* cost of such spillovers to healthy borrowers

As De Jonghe et al. (2020) show, both have important, yet distinct implications for bank lending.

Table 4: Sector specialization and information advantage: controlling for soft and hard information

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies when controlling for various hard and soft information proxies. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Columns 1, 4, and 7), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Columns 2, 5, and 8), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Columns 3, 6, and 9). The independent variables are bank specialization, the interaction between bank specialization and a dummy indicator for zombie firms, the interactions between the zombie indicator and measures of soft information, and the interactions between bank specialization and measures of hard information. We capture soft information by the length of a firm-bank relationship, a share of a bank in a firm's total credit, and bank market presence. We capture hard information by the firm's total assets, leverage ratio, return on assets, current ratio, and age. The sample includes yearly firm-bank level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Continuous independent variables have been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

Bank×Year FE	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

are larger.

First of all, the *scope* for such spillovers will likely be larger, the more important zombie firms are in the sector and the more resources they lock up (such as labor, capital, and credit). It is rather unlikely that healthy firms endure negative effects from competing with zombie firms if these zombies take up only a marginal fraction of resources and market share. Specialized banks should be more aware of this and are therefore expected to curb zombie lending especially in sectors where zombies take up a meaningful share of resources. As a result, the performance and growth of healthy borrowers improve and, consequently, the portfolio quality of the bank improves.

Second, not only the scope for spillovers but also the opportunity costs of spillovers may matter. By providing additional credit to zombie borrowers, banks wish to benefit from hiding non-performing loans (Blattner et al., 2018), avoiding capital loss (Acharya et al., 2019) or extracting higher profits from bad borrowers in the future (Schäfer, 2019). On the other hand, banks also face the opportunity cost of lending to zombie firms. By granting additional credit and enabling zombie firms to stay afloat, banks impose a higher risk of negative zombie spillovers on healthy borrowers. The cost of these spillover effects increases with the sector's growth prospects as the growth distortion due to zombie congestion is more palpable in those sectors. Hence credit reallocation from zombies to healthy firms induced by superior sectoral information is going to be especially valuable in sectors with better growth prospects. Moreover, by allocating more credit to productive firms, banks further contribute to the sector productivity boost (Bai et al., 2018) and help to sustain the sector growth and benefit from it as it widens the pool of high-quality borrowers that would bring more positive-NPV projects for a bank.

To test each of these two conjectures, we modify the baseline Equation 1 and add a triple interaction. First, we interact the $Z \times Specialization$ term with the share of labor sunk in zombies in the sector[10] when testing the scope for congestion hypothesis. Second, we interact the $Z \times Specialization$ with the sector's *expected* turnover growth (proxied by the sector's median firm

[10]Labor is our preferred measure of zombie market share for two reasons. Firstly, labor is more sticky than capital (i.e., tangible assets) or credit and is, therefore, less endogenous with respect to changes in bank credit supply. Secondly, labor is more scarce than capital and credit within the economy. Hence, if more labor is trapped in zombie firms, less labor is available to healthy firms. Therefore, the sector share of zombie labor is more correlated with the negative effect of resource misallocation inflicted on healthy firms.

turnover growth in *t+1*) when testing the opportunity cost of spillovers.

The coefficient on the triple interaction term is expected to be negative in both tests. Together with the baseline effect, this would indicate that banks tend to reduce zombie lending in sectors where they are more specialized, and especially so if zombie firms lock up a higher fraction of labor in that sector and/or if the growth prospects of the firms in that sector are better.

Table 5: Scope for zombie spillover risk: labor sunk in zombies

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies allowing for heterogeneity due to sectoral differences in zombie congestion. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization, a dummy indicator for zombie firms, the share of labor sunk in zombies at the sector-year level, as well as their possible interactions. The sample includes yearly bank-firm level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Continuous independent variables have been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

The results in Table 5 suggest that banks, indeed, tend to reduce lending relative more to zombie firms operating in sectors, where banks are more specialized (the baseline effect), and this effect amplifies with a higher share of zombie labor in that sector. In other words, relative to a healthy borrower in the same sector, a zombie faces an even more limited credit supply from a specialized bank if the sector is more congested by zombie firms. This channel is more pronounced

at the intensive margin of credit growth (Columns 2 and 3).

Likewise, the results in columns 2 and 3 of Table 6 also reveal that ceteris paribus, specialization induces banks to curb zombie lending proportionally more in sectors that are expected to grow faster in terms of turnover (negative triple interaction term).

Table 6: Opportunity costs of spillover risk: sector growth

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies allowing for heterogeneity due to sectoral differences in sales growth. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization, a dummy indicator for zombie firms, the share of labor sunk in zombies at the sector-year level, as well as their possible interactions. The sample includes yearly firm-bank level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. Bank×Year FE	Yes	Yes	Yes

Overall, these two tests indicate that the negative relationship between bank specialization and zombie lending in a given sector becomes more apparent when the scope and opportunity cost of zombie congestion is larger. Banks tend to 'de-zombify' economic sectors, in which they are more specialized, when the resources sunk in zombies increase and when the growth prospects of that sector are better. Bank specialization and information acquisition facilitate a more efficient resource reallocation.

5.3. Loss aversion motive

In the previous section, we have shown that the information advantage induces banks to cut zombie lending more if the potential benefit to healthy firms is larger. In this section, we document the presence of an alternative channel, *loss (given default)-aversion*, which induces banks to cut zombie lending less because triggering default of zombies is likely to hurt (collateral values of) healthy firms.

Firms pledge collateral to reduce the loss given default. However, if this collateral consists of less redeployable assets (more firm- or industry-specific assets), it may not only affect the repossession value of the claims on the defaulting firm. If assets are more difficult to sell, and especially outside their original industry, then selling them at a substantial discount (fire-sale prices) drives down the market value of the collateral of other firms in the same industry (e.g., Giannetti and Saidi, 2019; Almeida et al., 2011; Acharya et al., 2007)[11]. A specialized bank might therefore be less willing to cut credit to zombie firms if the bank expects the firm's assets to be liquidated at a significant discount, with spillover effects to healthy firms. Put differently, thanks to the information advantage due to specialization, a specialized bank is better aware of the consequences of collateral liquidation[12] on its other borrowers, which may affect the bank's decision to lend to zombie borrowers.

To test this conjecture we again add a triple interaction to our baseline regression model in Equation 1, this time with a measure of sector asset specificity. More specifically, we follow Giannetti and Saidi (2019) and Acharya et al. (2007) and measure sector asset specificity as the ratio of the total value of machinery and equipment in a given two-digit sector relative to the total value of total assets in the sector.[13] The coefficient of interest is the triple interaction between the zombie indicator, bank specialization, and sector asset specificity. If the sign of the coefficient is positive,

[11]Benmelech and Bergman (2011) introduce the "collateral channel" to explain the negative externalities of bankrupt firms on nonbankrupt competitors. According to this channel, bankruptcies reduce the collateral value of the nonbankrupt firms within a sector, and the higher illiquidity of assets amplifies this effect.

[12]Gopal (2021) also provides evidence of banks specializing in different types of collateral. This collateral specialization reduces information asymmetry and facilitates better credit access of firms that pledge collateral, in which a bank is more specialized.

[13]The reasoning for proxying for asset specificity with machinery and equipment ratio is the following. Being movable collateral, machinery and equipment are less valuable than immovable real estate. Furthermore, machinery is deemed as more sector-specific and often custom-made, which makes it more difficult to sell at fair value in the case of liquidation.

it means that if a bank is better aware (thanks to higher specialization) of the lower redeployability of the assets in a sector and hence the larger impact on healthy borrowers, the bank is less willing to cut zombie credit in that sector. The results of this exercise are presented in Table 7.

Table 7: Loss aversion motive: the role of sector asset specificity

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies allowing for heterogeneity due to sectoral differences in asset specificity. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization, a dummy indicator for zombie firms, the ratio of aggregate machinery and equipment to aggregate total assets (at the sector-year level), as well as their possible interactions. The sample includes yearly firm-bank level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Continuous independent variables have been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

Firm×Year FE	Yes	Yes	Yes
Bank×Year FE	Yes	Yes	Yes

The results of the test show that specialized banks tend to provide relatively more credit to zombie firms operating in sectors with more specific assets. This effect is more evident at the intensive margin of credit growth. For example, in columns 2 and 3, we can see that the net effect of bank specialization turns positive for zombie firms borrowing from banks that are more specialized in sectors with higher sector specificity.

Interesting to note here is the (mostly) insignificant, negative interaction term between bank specialization and assets specificity in Table 7. Specialized banks do not treat healthy firms in low

or high-asset specificity sectors differently, as these firms have a substantially lower probability of default (and hence the risk of contagious revaluation due to asset fire sales is lower).

5.3.1. Loss aversion motive: large zombies

Zombie lending is argued to be pervasive in order to avoid an impact on bank solvency. Zombies that account for a large share in the bank's total lending (and are thus important to the bank) might be protected more as their default would have a larger impact on bank solvency. We would therefore expect zombie firms that are larger from the bank's perspective, to enjoy a more generous credit supply.

The role that bank specialization is expected to play for large zombies is ex-ante less clear. On the one hand, large zombies –by definition– take up a large fraction of sectoral resources and thereby increase the scope for negative spillovers. If this effect is dominant, we would expect the reduction in zombie lending from specialized banks to be stronger for larger zombies. On the other hand, the default of a large zombie is more likely to have an impact on sectoral asset values, and hence be contagious for healthy borrowers, than a default of a small zombie. If this effect is dominant, we would expect the reduction in zombie lending from specialized banks to be weaker for larger zombies.

To investigate this, we once more add a triple interaction to our baseline regression model in Equation 1. This time we add an interaction term with the lagged share of credit granted by the bank to a firm in the bank's total corporate credit in a given year, *Firm Share*. The latter proxies for the firm's importance to a bank. Note that, because *Firm Share* is varying at the bank-firm level, we also include it separately in this regression model, as well as its interactions with Z and *Specialization*. Also note that, in previous triple interaction models, the stand-alone inclusion of the characteristic under study and its interaction with Z were subsumed by the firm×year fixed effects.

Firstly, given the positive sign of the interaction term Z×Firm Share, zombie firms seem to enjoy a more generous credit supply when they make up a bigger share of the bank's total credit. Thus,

Table 8: Loss aversion motive: interaction with firm's share in bank portfolio

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies allowing for heterogeneity due to the importance of a firm to a bank. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year t and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization, a dummy indicator for zombie firms, the share of firm credit in the banks' corporate credit portfolio, as well as their possible interactions. The sample includes yearly firm-bank level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Continuous independent variables have been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

N. of clusters	1774	1774	1774
Firm×Year FE	Yes	Yes	Yes
Bank×Year FE	Yes	Yes	Yes

banks tend to protect important zombie borrowers from a credit dry-up. This finding suggests that banks seem to avoid larger write-offs by providing more liquidity to zombie borrowers that account for a larger share of the bank's total credit portfolio.

The effect of the triple interaction term is negative, and therefore suggests that specialized banks reduce zombie lending even more if the zombie borrower is large. This is in line with specialized banks being more concerned and aware of the negative impact that (large) zombie firms have on healthy borrowers. Note, however, that the net effect of being a large zombie borrower is still positive. Hence, while the motive of banks to protect more important zombie borrowers remains strong for an average bank, it is weaker for banks with better sector information.

6. Robustness tests of the baseline specification

In this section, we revisit the baseline specification (i.e., Equation 1 and Table 2) and discuss several robustness checks. For space and clarity, we keep this section intentionally focused and put all tables in Appendix G. We focus on four potential concerns with the baseline specification: (i) firm-bank matching and credit demand, (ii) aggregate effects (iii) measurement of bank specialization, and (iv) the role of bank health and crisis episodes.

6.1. Firm-bank matching and credit demand

The baseline Equation 1 includes firm×year fixed effects and thus controls for any observed and unobserved heterogeneity at the firm-year level. However, that does not rule out potential distortions due to (historic) firm-bank matching.[14] Moreover, we look at total credit at the firm-bank level, which pools together various products that differ in the degree to which they are callable by the bank (due to differences in maturity, covenants, etc.). Biases in the estimation results might thus also occur if the choice of bank products by firms is correlated with bank specialization (and would result in bank-specific credit demand, as in Paravisini et al. (2017)).

[14] In Table 4, we already included some variables at the firm-bank level (such as relationship length and the share of the bank in firm's credit) that might account for biases due to the firm-bank matching. Here, we provide further tests using a homogeneous product.

To mitigate these concerns, we proceed in two steps. We first redo the analysis on one specific product that is homogeneous across banks and firms, namely *overdraft facilities*. At the expense of sample size and generalizability, we increase identification. The results in columns 1, 3, and 5 of Table G.1 show that our results also apply for this homogeneous product and a much smaller sample of firms that have such a product with at least two banks.

Subsequently, we add two other sets of fixed effects to this specification applied to this homogeneous product (overdraft facilities). Like Paligorova and Santos (2017); Altavilla et al. (2020); Schivardi et al. (2021), we include firm×bank fixed effects to control for non-random matching between firms and banks. In addition, we also include bank×sector×year fixed effects, to further strengthen identification (e.g., capturing bank-sector specific credit supply shocks, such as capital requirements due to concentration risk). Columns 2, 4, and 6 of Table G.1 show that the impact of specialization on credit supply to zombie firms is negative and significant (at the intensive margin) in a specification on a homogeneous product with fixed effects that control for bank-firm matching.

6.2. Aggregate effects

The baseline results come from an unweighted regression that gives equal weight to each observation. To account for the importance of each observation and get closer to the aggregate impact, we estimate weighted regressions (ceteris paribus) using the firm's total assets as weights. The coefficients of the interaction effect are slightly smaller but are still significantly different from zero.

The inclusion of firm×year fixed effects is common practice in studies that use credit register data as it allows separating demand and supply effects. However, it implies that we restrict the sample to multiple-bank firms. In the Belgian credit market, most borrowers have a single-bank relationship, which may cast doubt on the generalizability of the results. Following Degryse et al. (2019), we bin together single-bank firms in sets of firms that can be assumed to have similar credit demand. In particular, we create, for each year, triplets based on the firm's location, firm's industry, and zombie status. Using these location×industry×zombie×year fixed effects to control for single-bank borrowers' credit demand expands the sample with a factor of 2.5. Trading of identification with representativeness, we still find quantitatively and qualitatively similar results.

6.3. Measuring specialization

In Table G.3, we present results using alterations of the independent variable of interest *Bank Specialization*. In panel A, we use a dummy variable approach to measure specialization. The dummy takes the value of one if $Specialization_{bjt-1}$ is in the top decile of that sector j in year *t-1*, and zero otherwise. As in Berthou et al. (2021), we find that the 90% cutoff is akin to using the cutoff as in Paravisini et al. (2017). We find that our main results remain and even become larger in economic magnitude.

Second, specialization is a proxy for the sector-specific soft information that banks acquire. However, theoretically, a large exposure to a sector could be driven by a handful of large borrowers, limiting the scope of learning through repeated interaction with firms in a given sector. Therefore, we alternatively compute specialization based on the number of borrowers in a sector, rather than the volume lent to a sector. More specifically, in panel B, we compute specialization as the fraction of the number of borrowers a bank has in a given sector relative to the total number of borrowers a bank has in a given year. We obtain similar results, which is not surprising as this measure is strongly correlated with the baseline specification measure ($corr = 0.8$).

Third, using two-digit NACE codes might be too granular, and acquired information might be useful for making decisions in related industries (sharing the first digit). Measuring specialization in bank lending at the one-digit NACE level (16 industries) in panel C, we show again that our main findings are robust to this alteration. Fourth and finally, utilities (electricity, water supply, and waste collection) and commercial real estate play a central role as input for many other sectors and may be more affected by state regulation or subsidies. As such, learning and knowledge acquisition may play a lesser role in credit allocation towards these firms. The results in panel D document that excluding these sectors from the sample and recomputing the specialization measure also does not affect our main results.

6.4. Bank health and crisis periods

We are the first to focus on the role of information acquisition (through sector specialization) on the credit supply to zombie firms. Previous research mainly focused on bank health and bank crises as a crucial factor in heterogeneous lending decisions towards healthy, less productive, and zombie

firms. For example, Albertazzi and Marchetti (2010) and Schivardi et al. (2021) document that undercapitalized banks in Italy were more likely to keep lending to low-quality borrowers during the financial crisis in 2008. Likewise, Giannetti and Simonov (2013) show that bank undercapitalization fosters lending to zombie firms in Japan. The rationale here is that banks that struggle to meet regulatory capital requirements will be less willing to recognize losses on bad loans.

Next to bank capital, also profitability (Bonfim et al., 2021) and bank size (Albertazzi and Marchetti, 2010) have been shown to affect zombie lending. As bank specialization might be correlated with bank capital, profitability, and size (see Beck et al., 2021), it is important to test whether bank specialization remains an important channel affecting zombie lending despite including an interaction with the other important drivers of zombie lending.

Similarly, the recovery from a (financial) crisis usually features an increasing share of zombies, a strategic reorientation by banks, and a credit contraction. It is thus important to verify whether our results are time-varying and episode-specific. We use a fairly long time period to make the results as general as possible, but are able to analyze whether there is a differential impact in (i) the period prior to the global financial crisis (2004-2007), (ii) the period spanning the global financial crisis and the sovereign debt crisis (2008-2013), and (iii) the post-crisis period (2014-2018).

Including interactions of the zombie dummy with various bank characteristics and triple interactions between bank specialization, zombie status, and (post-)crisis period dummies leave the coefficients of interest largely unaffected. If anything, we even notice an economically larger effect.

7. Conclusion

This paper contributes to the discussion of zombie congestion and zombie lending using loan-level data for the universe of firms and banks in Belgium between 2004 and 2018. We develop a new approach to identify zombie firms and uncover a previously unexplored determinant of zombie lending, namely bank specialization.

Overall, our findings convey two interesting and important messages. First of all, the choice of how zombie firms are identified is important, as it may lead to substantial differences in the estimated zombie population, both in terms of the number of zombie firms and the quality of

zombie firms. Compared to the widely-used OECD definition (McGowan et al., 2018), our approach identifies much fewer firms as zombies (4% of the population instead of 9%) and they are of much lower quality than healthy firms. Nonetheless, despite documenting that there are relatively fewer zombie firms in Belgium than what other studies have found, we find that i) some sectors have significant, above average amounts of zombie firms; and ii) having more resources stuck in zombie firms still exerts negative effects on healthy firms.

Secondly, we provide evidence on the effect that bank specialization has on zombie lending. We show that bank specialization is associated with lower and even reduced credit supply to zombie borrowers. Banks that are specialized in lending to a certain sector have gained an information advantage that makes them more aware of zombie firms in the sector as well as more knowledgeable about the negative impact that zombie firms have on healthy borrowers.

Our analysis shows that this information channel is indeed sector-specific and different from borrower-specific hard or soft information. Moreover, specialized banks reduce zombie lending even more when the scope and opportunity cost of negative spillovers to healthy borrowers is larger; namely, when the fraction of sectoral labor stuck in zombie firms is larger or when the sector is expected to grow faster. Additionally, specialized banks reduce zombie lending more in sectors with low asset specificity than with high specificity. In sectors with high asset specificity, it is relatively more likely that a zombie firms' default would lead to its assets being sold at a significant discount and hence more likely to contaminate the value of healthy borrowers' collateral.

Our results imply that bank specialization can benefit financial stability as it reduces zombie lending. As such, it not only improves the quality of the bank's lending portfolio by increasing the relative share of credit going to healthy borrowers, it also improves the business climate for the healthy borrowers as they now need to compete with fewer zombie firms (or at least with zombie firms that congest fewer resources). Our study, however, does not claim that a lending specialization of 100% should be preferred for banks as we only provide a partial analysis rather than a general equilibrium approach. Our results merely show that there are also benefits to divert from a full diversification.

Our findings are also relevant in the current circumstances of the ongoing COVID-19 crisis.

Given the detrimental effect of the confinement measures on the liquidity of the corporate sectors (OECD, 2020), we should expect an increase in non-performing loans (NPLs) (Ari et al., 2020). However, according to Ari et al. (2020), many NPLs are expected to come from viable, yet illiquid firms rather than from zombie firms. Therefore, banks' expertise and screening abilities become especially important to identify truly viable firms and negotiate the term of debt restructuring in a way that supports the economic recovery.

Finally, while 'killing' zombie firms would improve resource allocation and bring about productivity gains, this should likely not happen overnight (Schivardi et al., 2021). Despite the economic gains that will follow in the long run when zombie firms exit the market, a sudden closure of multiple enterprises may have a negative effect on the economy. Firstly, it may cause capital destruction and negative spillovers to firms both within and outside the economic sector, where a mass shut-down is happening. Sudden mass closure of businesses may lead to fire sales (e.g., Shleifer and Vishny, 1992) of assets and collateral below the fair prices, which drives down the collateral value of other firms in the sector and exacerbates their financial constraints (Kiyotaki and Moore, 1997). Additionally, fire sales harm firms' creditors (Acharya et al., 2007) and may have a negative spillover to other sectors via the supply chain channel (e.g., Giannetti and Saidi, 2019). Moreover, the costs of worker displacement should be taken into account as discussed by Andrews and Saia (2016). A large and sudden business shut-down may increase unemployment. Hence, banks and policymakers need to take the economic side effects into account when developing a strategy to reduce the population of zombie firms.

Appendix A. Definitions of Variables

Table A.1: Variable definitions

Credit Variables	
New Loan	A dummy = 1 if authorized credit L_{bft} granted by bank b to firm f in year t exceeds the authorized credit amount in year *t-1* and 0 otherwise.
ΔLn(Credit)	$= Ln(L_{bft}) - Ln(L_{bft-1})$
$\frac{\Delta\text{Credit}}{\text{Assets}}$	$= \frac{L_{bft} - L_{bft-1}}{TotalAssets_{ft-1}}$
Bank-Sector Variables	
Specialization	$= \frac{\sum_{f=1}^{F} L_{bfst}}{\sum_{s=1}^{S}\sum_{f=1}^{F} L_{bfst}}$, the fraction of bank's b credit L_{bfst} granted to all firms sector s in year t in the bank's total credit granted to all sectors in that year.
Presence	$= \frac{\sum_{f=1}^{F} L_{bfst}}{\sum_{b=1}^{B}\sum_{f=1}^{F} L_{bfst}}$, the fraction of bank's b credit L_{bfst} granted to all firms in sector s in year t in the total credit granted to that sector by all banks.
Sector Variables	
Z^{Credit} Share	$= \frac{\sum_{f=1}^{F} \text{Credit}_{fs}\|Z=1}{\sum_{f=1}^{F} \text{Credit}_{fs}}$, the fraction of credit granted to zombie borrowers in the total amount of credit granted to all companies in sector s.
Sector Growth	Median turnover[15] growth of companies operating in a sector in year *t+1*.
Z^{Labor} Share	$= \frac{\sum_{f=1}^{F} \text{FTE}_{fs}\|Z=1}{\sum_{f=1}^{F} \text{FTE}_{fs}}$, the fraction of labor force (FTEs) sunk in zombie borrowers in the total number of FTEs employed by all companies in sector s.
Specificity	$= \frac{\sum_{f=1}^{F} Machinery_{fs}}{\sum_{f=1}^{F} Assets_{fs}}$, the share of total machinery and equipment in total assets in sector s.

[15]Small and medium-sized enterprises do not have to report the turnover figures in the income statement. Therefore, we draw the turnover data from monthly VAT filings.

Variable definitions: continued

Firm Variables	
Equity/Assets	Firm's leverage ratio
Negative Equity	A dummy = 1 if firm's equity is negative and 0 otherwise
EBITDA/Assets	Return on Assets
Altman Z	$= 0.717 \times \frac{WorkingCapital}{TotalAssets} + 0.847 \times \frac{RetainedIncome}{TotalAssets} +$ $3.107 \times \frac{EBIT}{TotalAssets} + 0.42 \times \frac{Equity}{Debt} + 0.998 \times \frac{GrossMargin}{TotalAssets}$
TangAssets Growth	Current growth of fixed tangible assets (TangA): $Growth_t = (TangA_t - TangA_{t-1})/(0.5 \times (TangA_t + TangA_{t-1}))$
Employment Growth	Current growth of FTE
Sales Growth	Current growth of turnover
Future Sales Growth	Future growth of turnover (Sales): $Growth_t = (Sales_{t+1} - Sales_t)/(0.5 \times (Sales_{t+1} + Sales_t))$
Z	A dummy = 1 if a firm is identified as a zombie according to the our zombie definition described in section 3 and 0 otherwise
Healthy	A dummy = 1 if a company a firm is *not* identified as a zombie according to the adjusted zombie definition and 0 otherwise
Ln(Assets)	Logarithm of firm's total assets
Current Ratio	= Current Assets/Current Liabilities
Age	Number of years since firm's year of incorporation
Bank-Firm Variables	
Firm Share	$= \frac{L_{bft-1}}{\sum_{f=1}^{F} L_{bft-1}}$, the fraction credit granted by bank b to firm f relative to the total credit granted by the bank to all firms.
Ln(Relationship)	Logarithm of the number of months since the first time firm f obtained a loan from bank b.
Bank Share	$= \frac{L_{bft-1}}{\sum_{b=1}^{B} L_{bft-1}}$, the fraction credit granted by bank b to firm f relative to the total credit granted to that firm by all banks.
Bank Variables	
Ln(Assets)	Logarithm of bank total assets
Capital Ratio	Common Equity/Total assets
Liquidity Ratio	(Cash + Interbank Assets)/Total assets
ROE	Return on Equity = Net income/Common Equity

Appendix B. Summary Statistics

Appendix B.1. Summary statistics of the main sample

Table B.1: Summary statistics

This table presents summary statistics of the variables used the analysis presented in section 4 onward. The sample includes yearly bank-firm level data between 2004 and 2018. The sample includes firms borrowing from more than one bank.

	N	Mean	SD	p1	p25	p50	p75	p99

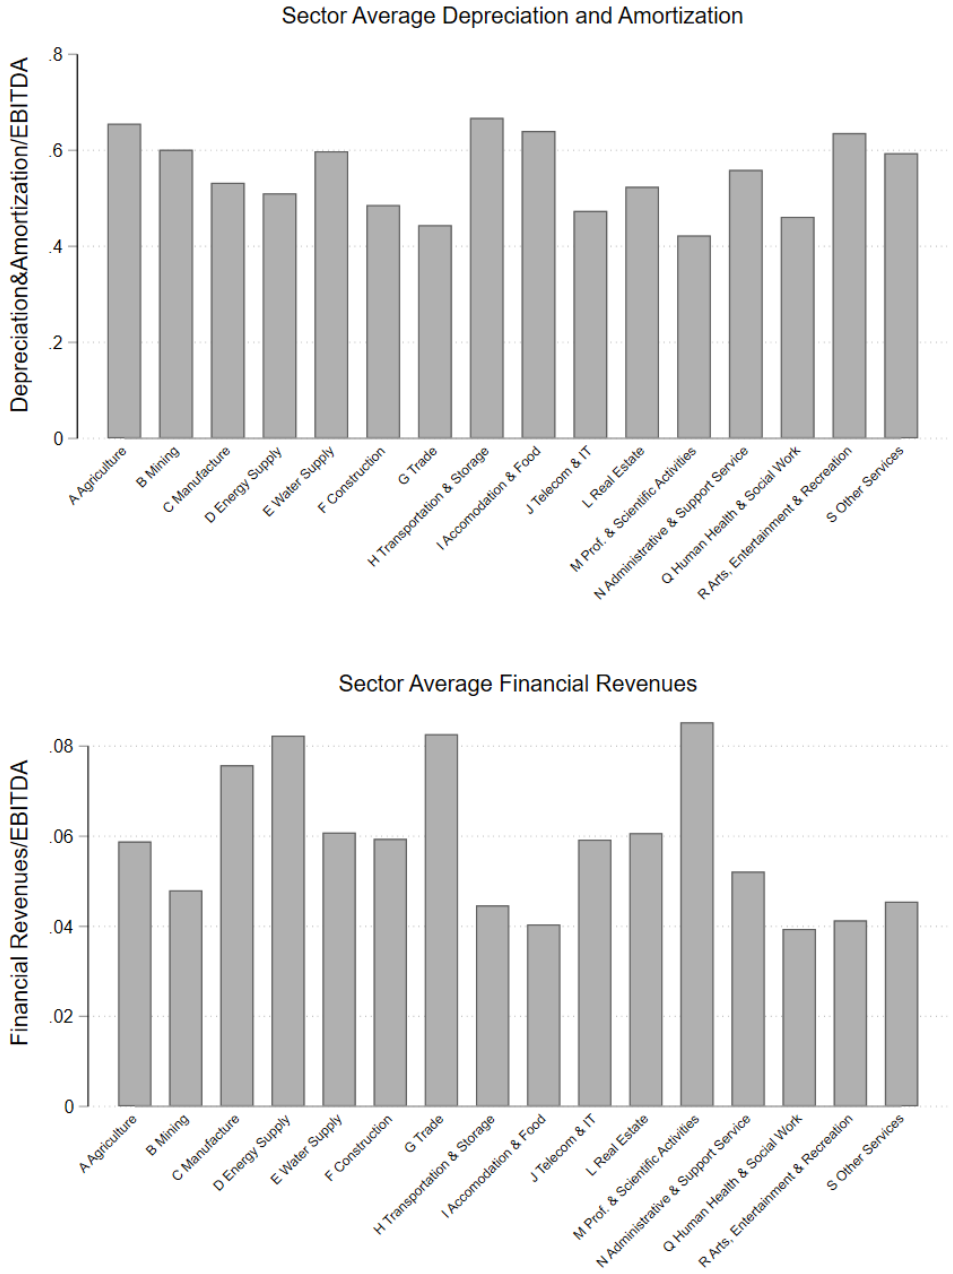
Age	275122	20.09	11.70	3.00	11.00	18.00	27.00	49.00

Appendix C. Share of Depreciation and Amortization and Recurring Financial Income in EBITDA

Figure C.1: Share of depreciation and amortization and financial income in EBITDA

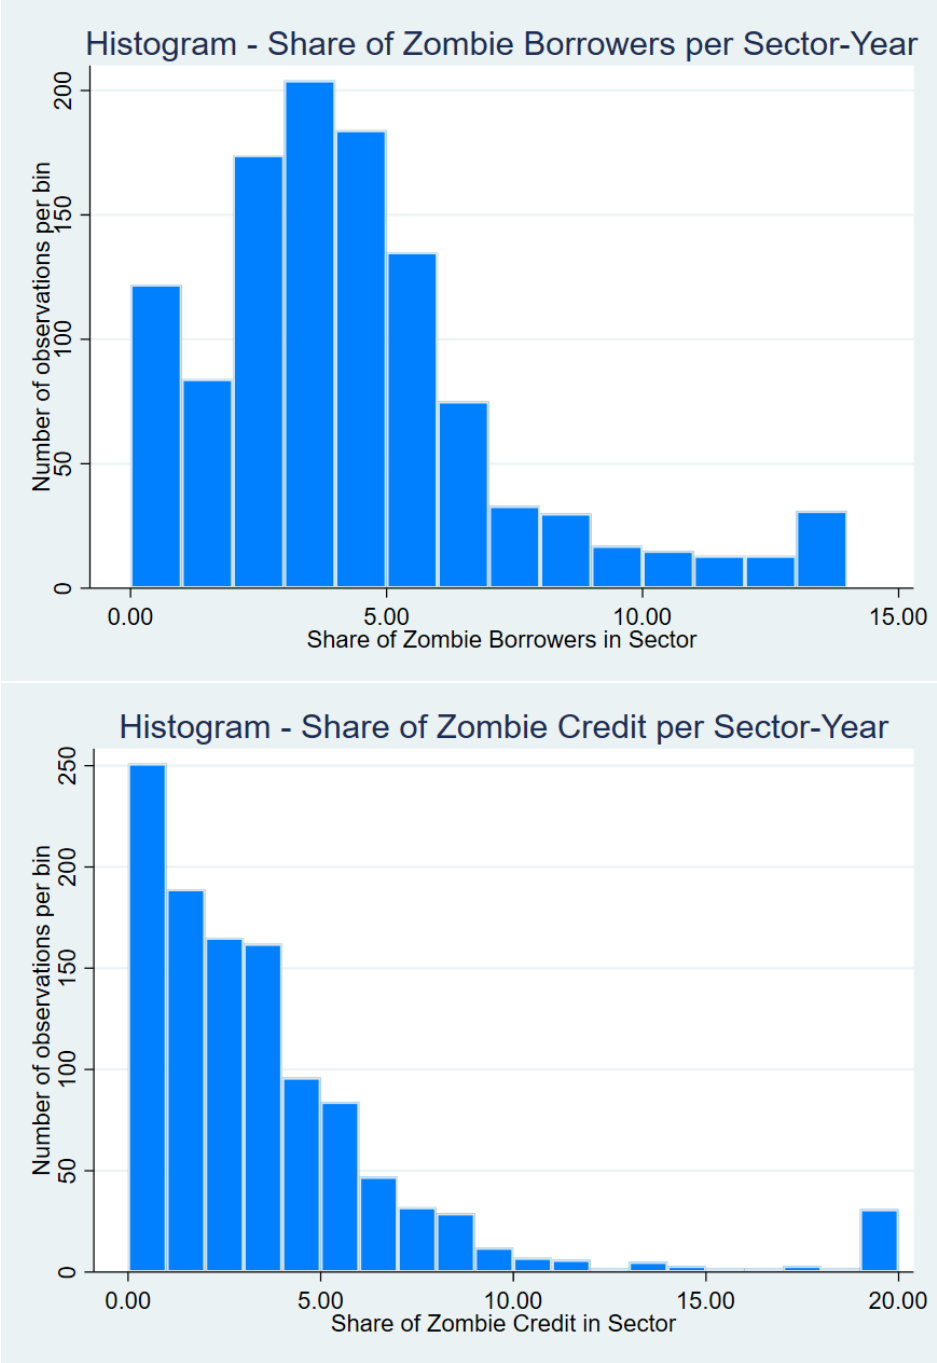
The figures below plot the share of depreciation and amortization in EBITDA (upper graph) and the share of recurring financial revenue in EBITDA (lower graph) for various economic sectors defined at the first digit of the NACE classification. The reported shares are time-average values. The sample includes yearly data of firms borrowing from more than one bank between 2004 and 2018.



Appendix D. Shares of Zombie Borrowers and Zombie Credit per Sector

Figure D.1: Zombie shares per sector

The plots below present distributional information on the shares of zombie borrowers (upper graph) and shares of zombie credit (lower graph). We compute these two shares for every economic sector (defined at the two-digit NACE classification) and every year in the sample (i.e., 2004-2018). The histogram shows on the X-axis the shares (binned in ranges of 1%) and on the Y-axis the number of sector-year combinations in that specific bin. Large values in the right tail have been binned together for clarity of presentation.



Appendix E. Zombie Congestion

Prior research shows a robust, negative relationship between the growth of healthy firms and the share of zombie firms in their sector (see, e.g., Caballero et al. (2008) who show this for Japan and McGowan et al. (2018) who document it for EU firms). However, Schivardi et al. (2020) document a serious, and difficult to solve, identification problem and even conclude that the correlation between healthy firm performance and zombie presence might be mechanical and biased. Solving this identification problem is not the purpose of the paper, but we nevertheless present empirical evidence of zombie congestion in our sample of Belgian firms. The results below present correlations and not causal evidence. Moreover, as the direction and magnitude of the bias are unclear and context-specific (Schivardi et al., 2020), we refrain from assessing the economic magnitude of the coefficients.

Table E.1 contains the results of estimating the following specification with the firm-year level data:

$$y_{it} = \beta_1 Healthy_{it} + \beta_2 Healthy_{it} \times Z^{Credit} Share_{jt-1} + \gamma X_{it-1} + \nu_{jt} + \upsilon_{st} + \epsilon_{ijt} \tag{E.1}$$

Where y_{it} is either growth of tangible fixed assets, employment, current sales, or future sales. The coefficient of interest is β_2, which is the interaction between a healthy firm dummy and the share of zombie credit in a sector. To be precise, *Healthy* is a dummy equal to 1 if a company is not identified as a zombie, and 0 otherwise. Z^{Credit} *Share* is the share of credit sunk in zombie companies in a sector j in a given year[16]. If a higher level of sector credit granted to zombie companies harms the growth of healthy borrowers operating in the same sector, the coefficient β_2 is expected to be negative.

The results of the estimation[17] are presented in Table E.1. Healthy borrowers exhibit higher

[16]Importantly, there is substantial variation in the share of zombie borrowers and zombie credit across years and sectors as can be seen in the histogram plot in Figure D.1. While the share of zombie credit in most sectors is relatively low, certain economic sectors suffer from more severe credit misallocation. For example, the sectors of the mining support service activities (NACE code 09), manufacture of motor vehicles (NACE code 29), waste collection (NACE code 38), and air transport (NACE code 51) are representing the right tail of the histogram.

[17]Firm-level controls include firm age, leverage, profitability, and total assets. Sector-year and firm location-year fixed effects absorb all observed and unobserved time-varying impacts of sectoral and locational characteristics such

growth in tangible assets, employment as well as current and future sales. However, the growth of healthy borrowers will be smaller if they operate in sectors where a larger fraction of credit is granted to zombie firms. The effects are statistically significant in three of the four columns. For reasons mentioned above, we mainly see this as suggestive evidence of zombie congestion as well as an exercise to show consistency (with prior research) in the Belgian context and using our zombie definition.

as product and credit demand.

Table E.1: Effect of zombie congestion on growth

This table shows the relative effect of the share of credit granted to zombie companies (Z^{Credit} *Share*) on the growth of the healthy (*Healthy*) companies relative to zombie companies operating in the same sector. The dependent variables are contemporaneous growth of tangible assets (Column 1), employment (Column 2), sales (Column 3) in period *t*, and future growth of sales in period *t+1* (Column 4). The independent variables of interest are the healthy company indicator, which equals 1 if a company is identified as a non-zombie and 0 otherwise, and the interaction term between the dummy for healthy companies and the share of credit granted to zombie borrowers in a given sector. Firm control variables include the leverage ratio, return on assets, the logarithm of total assets, and firm age in years. The sample includes yearly data of firms borrowing from more than one bank between 2004 and 2018. Sector-year and location-year fixed effects absorb time-varying sector- or location-specific differences in the dependent variables. Sectors are defined at the two-digit NACE level. Location is defined at the two-digit postcode level. Continuous independent variables are standardized. Standard errors are clustered at the sector-year level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

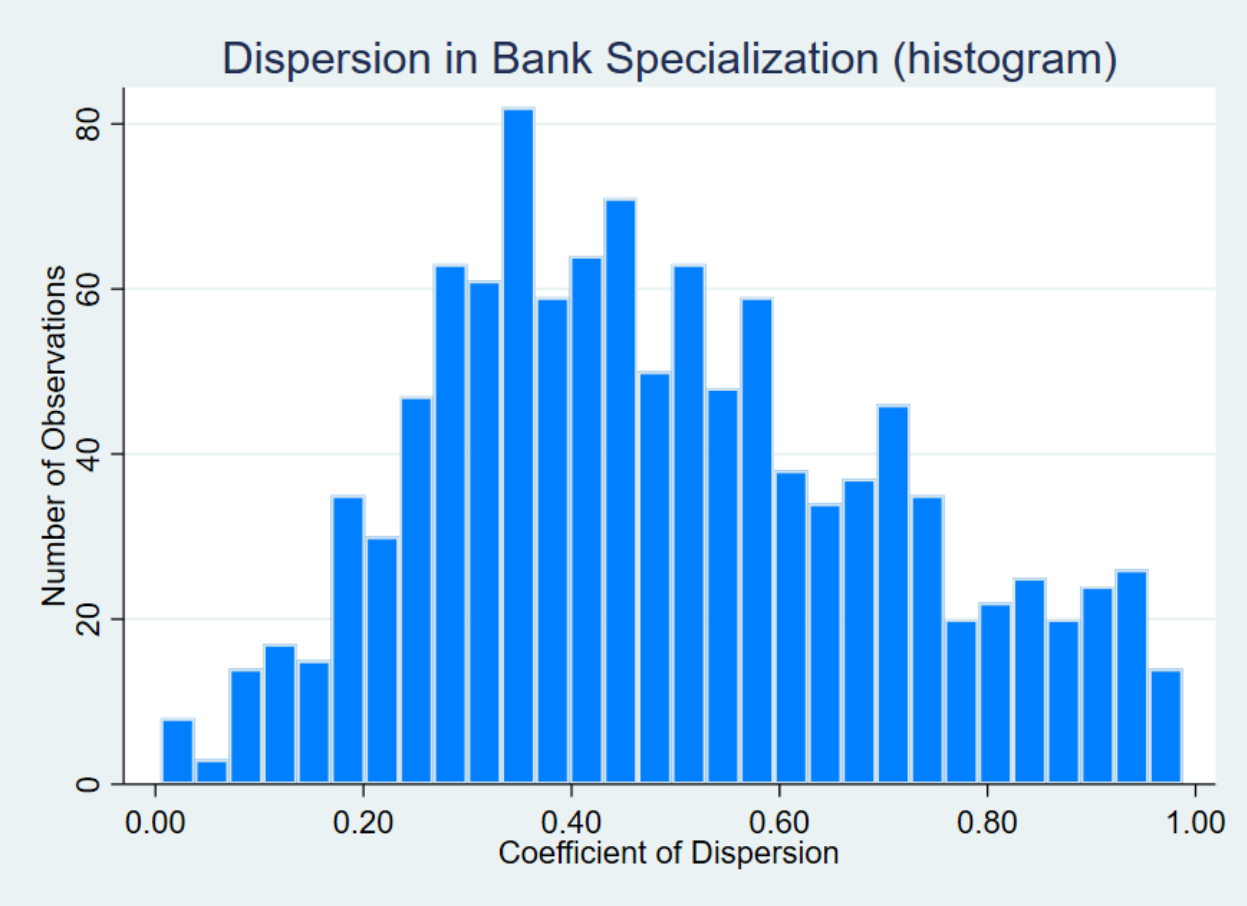
Appendix F. Distribution of Bank Specialization

Figure F.1: Bank specialization: histogram of coefficient of variation

This plot presents distributional information on within sector dispersion in bank specialization. For each sector and each year, we compute a modified quartile coefficient of dispersion*, as the ratio of the difference and the sum of the 90th and 50th percentile of bank specialization. The larger the coefficient of dispersion, the larger the within sector differences in bank specialization, and thus the larger the scope for informational advantages for the specialized banks. We compute this coefficient of dispersion for every economic sector (defined at the two-digit NACE classification) and every year in the sample (i.e., 2004-2018). The histogram shows on the X-axis bins of this coefficient of dispersion and on the Y-axis the number of sector-year combinations in that specific bin.



* The quartile coefficient of dispersion is usually computed based on the 75th and 25th percentile. Compared with the coefficient of variation, it is a robust measure of scale as it is not affected by outliers. We modify the percentiles to document the scope for information advantages of the most specialized banks in a sector.

Appendix G. Robustness Tests

Appendix G.1. Robustness of the baseline results: firm-bank matching and credit demand

Table G.1: Robustness: firm-bank matching and credit demand

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies for a standardized and homogeneous credit contract. In particular, we only consider one credit product, namely overdraft facilities. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization and the interaction between bank specialization and a dummy indicator for zombie firms. The sample includes yearly bank-firm level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. In all specifications, we control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Additionally, specifications in Columns 2, 4 and 6 include bank-firm and bank-sector-year fixed effects. Bank specialization has been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

Appendix G.2. Robustness of the baseline results: aggregate effects

Table G.2: Robustness: aggregate effects

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization and the interaction between the bank specialization and a dummy indicator for zombie companies. The sample includes yearly bank-firm level data between 2004 and 2018. We present two approaches to get at aggregate effects. In Panel A, the sample includes companies borrowing from more than one bank. We run a weighted regression with weights linked to each firm's total assets. In this panel, we control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. In Panel B, the sample includes all borrowing companies regardless of the number of bank relationships. In this panel, we control for firm demand and bank-specific effects using industry-location-zombie-year and bank-year fixed effects, respectively. In both panels, bank specialization has been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

Appendix G.3. Robustness of the baseline results: alternative specialization measures

Table G.3: Robustness: alternative specialization measures

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year t and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are various measures of bank specialization and the interaction between the bank specialization and a dummy indicator for zombie companies. We show the robustness of the results with respect to the construction of the specialization measure. In Panel A, we measure specialization as a dummy variable that takes the value of one if $Specialization_{bjt-1}$ is in the top decile of that sector j in year *t-1*, and zero otherwise. In Panel B, we compute specialization as the fraction of the number of borrowers a bank has in a given sector relative to the total number of borrowers a bank has in a given year. In Panel C, we measure volume-based specialization at the one-digit NACE level. In Panel D, we exclude electricity, water supply, waste collection, and commercial real estate from the sample and re-compute our baseline measure of bank specialization. The sample includes yearly bank-firm level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Bank specialization has been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

Appendix G.4. Robustness of the baseline results: bank health and crisis periods

Table G.4: Robustness: bank health and crisis periods

This table shows the effect of bank specialization on the credit growth of healthy firms and zombies. The dependent variables are a dummy variable that equals 1 if the outstanding credit amount increases and 0 otherwise (Column 1), the logarithmic difference between the outstanding credit amount in year *t* and year *t-1* (Column 2), and absolute change in the outstanding credit amount scaled to the borrower's total assets (Column 3). The independent variables are bank specialization, the interaction between the bank specialization and a dummy indicator for zombie companies, the interactions between a dummy indicator for zombie companies and bank-health variables, and the interactions between bank specialization, a dummy indicator for zombie companies, and dummy indicators for time periods. Bank-health variables include bank total assets, common capital ratio, liquidity ratio, and return on equity. We include two dummy indicators for time periods. The first one captures the crises episodes and equals 1 for years between 2008 and 2013 and 0 otherwise. The second one captures the post-crisis period and equals 1 for years between 2014 and 2018 and 0 otherwise. The sample includes yearly bank-firm level data between 2004 and 2018. The sample includes firms borrowing from more than one bank. We control for firm demand and bank-specific effects using firm-year and bank-year fixed effects, respectively. Bank specialization and bank-health variables have been standardized. Standard errors are clustered at the bank-sector level. ***, ** and * denote p<0.01, p<0.05, and p<0.1, respectively.

NATIONAL BANK OF BELGIUM - WORKING PAPERS SERIES

The Working Papers are available on the website of the Bank: http://www.nbb.be.

348. "Can inflation expectations in business or consumer surveys improve inflation forecasts?", by R. Basselier, D. de Antonio Liedo, J. Jonckheere and G. Langenus, *Research series*, October 2018.
349. "Quantile-based inflation risk models", by E. Ghysels, L. Iania and J. Striaukas, *Research series*, October 2018.
350. "International food commodity prices and missing (dis)inflation in the euro area", by G. Peersman, *Research series*, October 2018.
351. "Pipeline pressures and sectoral inflation dynamics", by F. Smets, J. Tielens and J. Van Hove, *Research series*, October 2018.
352. "Price updating in production networks", by C. Duprez and G. Magerman, *Research series*, October 2018.
353. "Dominant currencies. How firms choose currency invoicing and why it matters", by M. Amiti, O. Itskhoki and J. Konings, *Research series*, October 2018.
354. "Endogenous forward guidance", by B. Chafwehé, R. Oikonomou, R. Priftis and L. Vogel, *Research series*, October 2018.
355. "Is euro area lowflation here to stay? Insights from a time-varying parameter model with survey data", by A. Stevens and J. Wauters, *Research series*, October 2018.
356. "A price index with variable mark-ups and changing variety", by T. Demuynck and M. Parenti, *Research series*, October 2018.
357. "Markup and price dynamics: Linking micro to macro", by J. De Loecker, C. Fuss and J. Van Biesebroeck, *Research series*, October 2018.
358. "Productivity, wages and profits: Does firms' position in the value chain matter?", by B. Mahy, F. Rycx, G. Vermeylen and M. Volral, *Research series*, October 2018.
359. "Upstreamness, social upgrading and gender: Equal benefits for all?", by N. Gagliardi, B. Mahy and F. Rycx, *Research series*, December 2018.
360. "A macro-financial analysis of the corporate bond market", by H. Dewachter, L. Iania, W. Lemke and M. Lyrio, *Research series*, December 2018.
361. "Some borrowers are more equal than others: Bank funding shocks and credit reallocation", by O. De Jonghe, H. Dewachter, K. Mulier, S. Ongena and G. Schepens, *Research series*, December 2018.
362. "The origins of firm heterogeneity: A production network approach", by A. B. Bernard, E. Dhyne, G. Magerman, K. Manova and A. Moxnes, *Research series*, January 2019.
363. "Imperfect competition in firm-to-firm trade", by A. Ken Kikkawa, G. Magerman and E. Dhyne, *Research series*, January 2019.
364. "Forward guidance with preferences over safe assets", by A. Rannenberg, *Research series*, January 2019.
365. "The distinct effects of information technologies and communication technologies on the age-skill composition of labour demand", by S. Blanas, *Research series*, January 2019.
366. "A survey of the long-term impact of Brexit on the UK and the EU27 economies", by P. Bisciari, *Document series*, January 2019.
367. "A macroeconnomic model with heterogeneous and financially-constrained intermediaries", by Th. Lejeune and R. Wouters, *Research series*, February 2019.
368. "The economic importance of the Belgian ports: Flemish maritime ports, Liège port complex and the port of Brussels – Report 2017", by E. Gueli, P. Ringoot and M. Van Kerckhoven, *Document series*, March 2019.
369. "Does banks' systemic importance affect their capital structure and balance sheet adjustment processes?", by Y. Bakkar, O. De Jonghe and A. Tarazi, *Research series*, March 2019.
370 "A model for international spillovers to emerging markets", by R. Houssa, J. Mohimont and C. Otrok, *Research series*, April 2019.
371. "Estimation methods for computing a branch's total value added from incomplete annual accounting data", S. Vansteelandt, F. Coppens, D. Reynders, M. Vackier and L. Van Belle, *Research series*, April 2019.
372. "Do SVARs with sign restrictions not identify unconventional monetary policy shocks?", by J. Boeckx, M. Dossche, A. Galesi, B. Hofmann and G. Peersman, *Research series*, June 2019.
373. "Research and development activities in Belgium: A snapshot of past investment for the country's future", by S. Vennix, *Research series*, July 2019.
374. "State dependent fiscal multipliers with preferences over safe assets" by A. Rannenberg, *Research series*, July 2019.
375. "Inequality, the risk of secular stagnation and the increase in household debt", by A. Rannenberg, *Research series*, August 2019.
376. "Welfare effects of business cycles and monetary policies in a small open emerging economy", by J. Mohimont, *Research series*, October 2019.

377. "Learning about demand abroad from wholesalers: a B2B analysis", by W. Connell, E. Dhyne and H. Vandenbussche, *Research series*, November 2019.
378. “Measuring trade in value added with Firm-level Data, by R. Bems and A. K. Kikkawa, *Research series*, November 2019.
379. “Scrapping the entitlement to unemployment benefits for young labor market entrants: An effective way to get them to work?”, by B. Cockx, K. Declercq, M. Dejemeppe, L. Inga and B. Van der Linden, *Research series,* December 2019.
380. “The impact of Brexit uncertainties on international trade: Evidence from Belgium”, by E. E. Schmitz, *Research series*, December 2019.
381. “The heterogeneous employment outcomes of first- and second-generation immigrants in Belgium”, by C. Piton and F. Rycx, *Research series*, January 2020.
382. “A Dane in the making of European Monetary Union – A conversation with Niels Thygesen”, by I. Maes and S. Péters, *Research series*, May 2020.
383. “Multi-product exporters: Costs, prices and markups on foreign vs domestic markets”, by Catherine Fuss, *Research series*, June 2020.
384. “Economic importance of the Belgian maritime and inland ports – Report 2018”, by I. Rubbrecht and K. Burggraeve, *Document series*, July 2020.
385. “Service characteristics and the choice between exports and FDI: Evidence from Belgian firms”, by L. Sleuwaegen and P.M. Smith, *Research series*, July 2020.
386. “Low pass-through and high spillovers in NOEM: What does help and what does not”, by G. de Walque, T. Lejeune, A. Rannenberg and R. Wouters, *Research series*, July 2020.
387. “Minimum wages and wage compression in Belgian industries”, by S. Vandekerckhove, S. Desiere and K. Lenaerts, *Research series*, July 2020.
388. “Network effects and research collaborations”, by D. Essers, F. Grigoli and E. Pugacheva, *Research series*, July 2020.
389. “The political economy of financing climate policy – evidence from the solar PV subsidy programs”, by O. De Groote, A. Gautier and F. Verboven, *Research series*, October 2020.
390. “Going green by putting a price on pollution: Firm-level evidence from the EU”, by O. De Jonghe, K. Mulier and G. Schepens, *Research series*, October 2020.
391. “Banking barriers to the green economy”, by H. Degryse, T. Roukny and J. Tielens, *Research series*, October 2020.
392. “When green meets green”, by H. Degryse, R. Goncharenko, C. Theunisz and T. Vadasz, *Research series*, October 2020.
393. “Optimal climate policy in the face of tipping points and asset stranding”, by E. Campiglio, S. Dietz and F. Venmans, *Research series*, October 2020.
394. “Are green bonds different from ordinary bonds? A statistical and quantitative point of view”, by C. Ma, W. Schoutens, J. Beirlant, J. De Spiegeleer, S. Höcht and R. Van Kleeck, *Research series*, October 2020.
395. “Climate change concerns and the performance of green versus brown stocks “, by D. Ardia, K. Bluteau, K. Boudt and K. Inghelbrecht, *Research series*, October 2020.
396. “Daily news sentiment and monthly surveys: A mixed–frequency dynamic factor model for nowcasting consumer confidence”, by A. Algaba, S. Borms, K. Boudt and B. Verbeken, *Research series*, February 2021.
397. “A bigger house at the cost of an empty fridge? The effect of households' indebtedness on their consumption: Micro-evidence using Belgian HFCS data”, by Ph. Du Caju, G. Périleux, F. Rycx and I. Tojerow, *Research series*, March 2021.
398. “Low interest rates and the distribution of household debt”, by M. Emiris and F. Koulischer, *Research series*, March 2021.
399. “The interplay between green policy, electricity prices, financial constraints and jobs. Firm-level evidence”, by G. Bijnens, J. Hutchinson, J. Konings and A. Saint Guilhem, *Research series*, April 2021.
400. Economic importance of the Belgian maritime and inland ports – Report 2019”, by I. Rubbrecht, E. Dyne and C. Duprez, *Research series*, May 2021.
401 “The return on human (STEM) capital in Belgium”, by G. Bijnens and E. Dhyne, *Research series*, July 2021.
402. “Unraveling industry, firm and host-region effects on export behaviors of international new ventures and established exporters”, by I. Paeleman, S. A. Zahra and J. W. B. Lang, *Research series*, July 2021.
403 “When trust is not enough: Bank resolution, SPE, Ring-fencing and group support” by M. Dewatripont, M. Montigny and G. Nguyen, *Research series*, August 2021.
404 “Bank specialization and zombie lending”, by O. De Jonghe, K. Mulier and I. Samarin, *Research series*, November 2021.
